# Supplement A: Chinook Salmon Run Reconstructions for the East Fork Andreafsky River (Brood Years 1990-2005) and the Kogrukluk River (Brood Years 1977-2006) 

This document is drawn from the Appendix of Siegel (2017).

Methods are provided for run reconstructions of the Chinook Salmon populations in the East Fork Andreafsky River (brood years 1990-2005) and the Kogrukluk River (brood years 1981-2006), tributaries of the Yukon and Kuskokwim rivers, respectively. These time series include years with unreliable/missing weir data and age/sex sampling. This Appendix describes methods used to fill in data gaps to create a continuous time series for each population. When analyzed in conjunction, correlation of life history characteristics between the two populations (and possibly others in the future) could demonstrate representation of western Alaskan Chinook Salmon as opposed to being unique to each population. Thus, these run reconstructions will provide another tool to complement the combined population run reconstructions to investigate population dynamics of western Alaskan Chinook Salmon.

## METHODS

## Data Sources

The majority of data used for these analyses came from the escapement weir monitoring projects on the East Fork Andreafsky and Kogrukluk rivers and were gathered from published reports summarizing results from these projects. The East Fork Andreafsky River weir is run by the U.S. Fish and Wildlife Service (USFWS), and the Kogrukluk River weir is run by the Alaska Department of Fish and Game (ADFG). Weir operations are designed to produce unbiased escapement estimates as well as age, sex, and length distributions of the escapement estimates. Scales are collected and used to estimate age distributions. Sex is determined visually by weir crews on both rivers through secondary characteristics, including snout prominence in males and roundness of the belly and extension of the genital opening in females. For a more detailed description of weir sampling methods, refer to Mears (2015) for the East Fork Andreafsky River and Williams and Shelden (2011) for the Kogrukluk River.

Escapement estimates produced for the East Fork Andreafsky and Kogrukluk River populations by using a Bayesian approach to estimate missed migration were acquired from ADFG and USFWS, respectively. These estimates are considered the best available for both systems (superior to published estimates), although substantial uncertainty remains for a few years when the weirs were largely not
operational as a result of high water (Z. Liller, ADFG, personal communication; J. Mears, USFWS, personal communication).

Harvest data from the commercial, subsistence, and sport fisheries on the Yukon and Kuskokwim rivers were collected and reported by ADFG. Harvest data were apportioned by age-classes in both the Yukon and Kuskokwim rivers. These data were primarily gathered from published ADFG documents. Some harvest data were acquired as unpublished data from ADFG via communication with agency biologists.

## Terminology

Brood year: the year in which spawning took place to produce a cohort of fish of the same age.
Return year: the year in which a mature fish returns to spawn.
Escapement: fish that make it back to the spawning beds within a return year. In this case, it is defined as those individuals that make it past the escapement monitoring weirs.

Returns: mature fish in a return year that return to the river to spawn. The term includes those individuals that survive to escapement plus those that are harvested in the terminal fisheries within a single return year.

Brood recruits: all returns from a single brood year that survive to return to their respective river system. The term includes the escapement plus those fish that are harvested in the terminal fishery. Brood recruits mature and return at different ages over multiple return years.

## East Fork Andreafsky River Run Reconstruction (Brood Years 1990-2005)

Escapement.—Escapement estimates are provided for return years 1994-2012. For all return years except 2001, total escapement estimates were produced from weir data by using a stratified sampling method with a Bayesian approach to estimate missed sampling (J. Mears, USFWS, unpublished data). During these years, sampling was considered sufficient to characterize the run. During 2001, the weir was not running long enough to produce representative data. Thus, an escapement estimate from ADFG aerial survey conversions was used instead (Volk et al. 2009).

Weir age-sex-length (ASL) sampling was used by USFWS to produce estimates of the distribution of the escapement by age at maturity and sex. For all years except 2001, ASL sampling was considered sufficient to produce unbiased estimates of age and sex proportions. Accordingly, estimates from a stratified sampling approach published in the annual weir reports were used (USFWS 1995-1999 and 2003-2013). Although weir reports for return years 1999 and 2000 were not obtained, the data for those years were acquired directly from the agency (J. Mears, USFWS, unpublished data). The weir was largely nonoperational during the run in 2001, and thus the average age and sex proportions from the
years with quality weir data (1994-2000, 2002-2012) were used to estimate the age and sex distribution for that year. East Fork Andreafsky River escapement numbers by age and sex combinations (Table S.A.1) were calculated by multiplying estimated age and sex proportions by total escapement estimates.

Harvest and exploitation.-To estimate harvest, it was assumed that all populations in the lower stock group of the Yukon River were exploited proportionally in the fisheries below the confluence with the Andreafsky River. Harvest estimates for Yukon River stock groups in each fishing district were retrieved from the annual ADFG "Origin of Chinook Salmon in the Yukon fisheries" reports (ADFG 1996-2015). The published harvest data are apportioned by age-class (but not by sex within ages). Accordingly, we estimated annual harvest for each age-class separately (Table S.A.2) by using the following equation:

$$
H a_{y, a}=\frac{E a_{y}}{\left(E l_{y}+H u_{y}\right)} \times\left(H 1_{y, a}+H 2_{y, a} \times P_{y}\right)
$$

where $H a_{y, a}$ is the estimated harvest of the East Fork Andreafsky River stock in year $y$ for fish of age-class $a ; E a_{y}$ is the estimated East Fork Andreafsky River escapement; $E l_{y}$ is the estimated escapement of the lower stock group in the Yukon River (Hamazaki, in review); $H u_{y}$ is the estimated harvest of the lower stock group above the confluence with the Andreafsky River; $H 1_{y, a}$ is the estimated harvest of the lower stock group in district $1 ; H 2_{y, a}$ is the estimated harvest of the lower stock group in district 2 ; and $P_{y}$ is an annual estimate of the proportion of the district 2 harvest taken below the confluence with the Andreafsky River (L. Dubois, ADFG, unpublished data). Lower stock group harvest upstream of the confluence with the Andreafsky River $(H u)$ is estimated for each return year by subtracting the estimated lower stock group harvest below the confluence from the estimated total lower stock group harvest via the equation

$$
H u_{y}=H l_{y}-\left(H 1_{y}+H 2_{y} \times P_{y}\right)
$$

where Hl is the total estimated harvest for the total lower river stock group. Exploitation rate by age-class (Table S.A.3) was calculated by dividing age-specific harvest estimates by the estimates of age-specific returns (the sum of age-specific harvest and escapement estimates).

Returns.-Annual East Fork Andreafsky River returns by age-class and sex (Table S.A.4) were estimated as the sum of annual harvest estimates and annual escapement estimates. Each sex was assumed to be harvested at the same rate within an age-class. Thus, harvest estimates for each age-class were apportioned to each sex proportional to the estimated escapement. Brood year was calculated by
subtracting the age at maturity from the return year. The data were reorganized and presented by brood year returns (Table S.A.5).

Average age and productivity.-The average age of the escapement by return year and the average age of recruits by brood year (Table S.A.6) were estimated using the following equation:

$$
A=\frac{\sum n_{a} \times a}{N},
$$

where $A$ is the average age; $n$ is the number of fish of age $a$; and $N$ is the total number of fish of all ages. Productivity (Table S.A.6) was calculated as the number of returns from a brood year cohort divided by the escapement during the corresponding brood year. Productivity was found to peak in year 2000 while being below replacement levels during brood years in the mid-1990s, 2002, and 2004 (Figure S.A.1).

Changes in the average age of brood recruits and of the escapement over time were analyzed using ordinary least-squares linear regression for the total population and for males and females separately (Figure S.A.2). Although none of the Andreafsky River brood recruit models was significant ( $P<0.05$ ), all demonstrated trends toward a younger age of maturity. The average age of all brood recruits was estimated to have declined from 5.17 to 5.06 over brood years 1990-2005 ( $F=0.7036$; df = 1,$14 ; P=0.42$ ). The average age of male brood recruits was estimated to have declined from 4.92 to 4.72 ( $F=1.257$; df $=1,14 ; P=0.28$ ). Average age of female brood recruits was estimated to have declined from 5.61 to 5.51 ( $F=0.521$; $\mathrm{df}=1,14 ; P=0.48$ ).

Changes in the average age of the escapement were minimal and nonsignificant. Smaller changes in the average age of the escapement in comparison to returns were a consequence of a decline in ageselective harvests during the time period of analysis, allowing a higher proportion of older fish to survive to escapement (Table S.A.3). Average age of the total escapement was estimated to have decreased from 5.08 to 5.00 between return years 1994 and $2012(F=0.4503 ; \mathrm{df}=1,17 ; P=0.51)$. The average age of the male escapement was estimated to have decreased from 4.84 to 4.71 ( $F=0.6357$; $\mathrm{df}=1,17 ; P=$ $0.44)$. The average age of the female escapement was estimated to have stayed relatively constant, moving from 5.53 to 5.54 during the time series ( $F=0.0003$, $\mathrm{df}=1,17 ; P=0.99$ ).

## Kogrukluk River Run Reconstruction (Brood Years 1977-2006)

Escapement.-Escapement data for return years 1981-2013 were taken from ADFG estimates from the Kogrukluk River weir data produced using a stratified Bayesian approach to fill in for missed sampling when the weir was not operational (Z. Liller, ADFG, unpublished data). In the majority of
years, less than $20 \%$ of the escapement was estimated, allowing for relatively precise estimates. In a few years (1982, 1987, 1989, 2007, and 2012), more than $50 \%$ of the escapement was estimated, and thus escapement estimates for those years have a high degree of uncertainty.

For all years in the time series (with the exception of 2012), age and sex proportions of the escapement were estimated from weir ASL sampling (Molyneaux et al. 2009; Williams and Shelden 2010, 2011; Brodersen et al. 2013; Hansen and Blain 2013; Liller et al. 2015). For the majority of years, samples were considered sufficient to produce unbiased estimates for the entire escapement by using a stratified sampling approach. For seven return years (1987, 1989, 1992, 1993, 1994, 1998, and 2013), age and sex sampling was limited; thus, estimates may be inaccurate but were used due to the lack of a superior alternative. No stratified estimate was produced for 2013; therefore, the proportions utilized were straight sample proportions. Samples for 2012 were considered too inaccurate to use for age and sex proportions due to collection being limited to the very beginning and end of the run. Average age proportions estimated for the entire Kuskokwim River escapement were used for the 2012 Kogrukluk River age distribution estimates (Z. Liller, ADFG, unpublished data). These data did not have age-classes separated out by sex; thus, for 2012, escapement for each age at maturity was distributed by sex using the average proportion of each sex by age at maturity in the escapement calculated from years with quality age or sex distribution data (1981-1986, 1988, 1990-1991, 1995-1997, and 1999-2011). For all other years, Kogrukluk River escapement numbers by age and sex (Table S.A.7) were calculated by multiplying the estimated age and sex proportions by the total escapement estimates.

Exploitation by age-class.-Harvest in the Kogrukluk River was assumed to be proportional to harvest in the entire Kuskokwim River. Exploitation by age-class in the Kuskokwim River returns (Table S.A.8) was estimated by dividing estimates of harvest for each age-class in the Kuskokwim River terminal fisheries by estimates of the total return (Z. Liller, ADFG, unpublished data). Harvest estimates by age-class and sex (Table S.A.9) were calculated using the following equation:

$$
H_{y, a}=X_{y, a} \times \frac{E_{y, a}}{\left(1-X_{y, a}\right)},
$$

where $H_{y, a}$ is the harvest in year $y$ for fish of age-class $a ; E_{y, a}$ is the estimated escapement; and $X_{y, a}$ is the respective estimated exploitation rate. The published harvest data are apportioned by age-classes (but not by sex within age-classes); therefore, the above equation was applied within each age-class to produce individual age-class harvest estimates.

Returns.-Each sex within the same age-class was assumed to be harvested at the same rate. Returns by return year (Table S.A.10) were estimated by adding harvest and escapement together. Brood year was calculated by subtracting the age at maturity of individual spawners from the return year. The data were reorganized by brood year returns (Table S.A.11).

Average age and productivity.-Average age of the escapement for each return year and returns for each brood year (Table S.A.12) were estimated using the following equation:

$$
A=\frac{\sum n_{a} \times a}{N}
$$

where $A$ is the average age; $n_{a}$ is the number of fish of age $a$; and $N$ is the total number of fish in the return. Productivity (Table S.A.12) was calculated as the number of returns from a brood year cohort divided by the escapement during the corresponding brood year. Productivity was found to peak in brood years 1983 and 2000 while being below replacement levels during brood years in the early 1980s, early 1990s, and mid-2000s (Figure S.A.3).

Changes in the average age of brood recruits and of the escapement over time were analyzed using ordinary least-squares linear regression for the total population and for males and females separately (Figure S.A.4). The average age of all brood recruits was estimated to have declined from 5.37 to 5.12 over brood years $1977-2006(F=3.97 ; \mathrm{df}=1,28 ; P=0.057)$. The average age of male brood recruits was estimated to have declined from 5.07 to 4.82 ( $F=3.54$; $\mathrm{df}=1,28 ; P=0.070$ ). The average age of female brood recruits was estimated to have declined from 6.00 to $5.74(F=7.81 ; \mathrm{df}=1,28 ; P=$ 0.012).

Declines in the average age of the escapement were steeper than those of brood recruits. This is a result of age selectivity in the Kuskokwim River harvest becoming stronger after the year 2000 in our estimates (Table S.A.8). Average age of the total escapement was estimated to have decreased from 5.46 to 4.94 between return years 1981 and $2013(F=20.3$; df $=1,31 ; P<0.001)$. Average age of males in the escapement was estimated to have decreased from 5.18 to 4.64 between return years 1981 and 2013 ( $F=24.77$; df $=1,31 ; P<0.001$ ). The average age of females in the escapement was estimated to have decreased from 6.02 to 5.69 between return years 1981 and $2013(F=15.22 ; \mathrm{df}=1,31 ; P<0.001)$.

Supplementary Table S.A.1. Escapement estimates by sex and age-class for the East Fork Andreafsky River Chinook Salmon population. The first number in each age (e.g., 2.3) represents the number of winters spent in freshwater, and the second number (i.e., after the decimal) denotes the number of winters spent in salt water. Age-1.2 females may be misidentified males.

| Year | Male age |  |  |  |  |  |  |  | Males | Female age |  |  |  |  |  |  |  | Females | Escapement |

Supplementary Table S.A.7. Escapement estimates by sex and age-class for the Kogrukluk River Chinook Salmon population. All total escapement numbers are from Alaska Department of Fish and Game (ADFG) estimates, implementing Bayesian methods to estimate missed sampling (Z. Liller, ADFG, unpublished data). The 2012 age and sex proportions were assumed to be the same as estimates for the entire Kuskokwim River due to limited sampling (Z. Liller, ADFG, unpublished data). Age notation is defined in Table S.A.1.

| Year | Male age |  |  |  |  |  |  |  |  | Males | Female age |  |  |  |  |  |  |  | Females | Total |

${ }^{\mathrm{a}}$ Weir was inoperable for a majority of the season.
${ }^{\mathrm{b}}$ Age and sex composition represents stratified estimates from limited samples. Considered the best estimates available.
${ }^{\text {c }}$ Potential age errors.
${ }^{\text {d }}$ Estimated age and sex composition from the entire Kuskokwim River was used.
${ }^{\mathrm{e}}$ Age and sex composition represents samples collected only.

Supplementary Table S.A.8. Exploitation rate estimates (terminal harvest/return) by age-class, for each sex separately, and for the entire population (total) of Kuskokwim River Chinook Salmon (Z. Liller, Alaska Department of Fish and Game, unpublished data). Sample size for estimating harvest age proportions is presented. Only well-represented age-classes are shown, as limited samples of other ageclasses produced inaccurate estimates. Age notation is defined in Table S.A.1.

Supplementary Figure S.A.1. Estimated productivity (recruits per spawner) by brood year from run reconstruction for the East Fork Andreafsky River Chinook Salmon population. Brood year is defined as the year of the escapement that produced recruits. Spawners are estimated as the escapement above the monitoring weir in a single return year. Recruits are estimated as all returns (escapement plus harvest) originating from a single brood year. Replacement level is shown by the dashed line.

Supplementary Figure S.A.2. Estimated average (a) brood recruit age by brood year and (b) escapement age by return year for the Chinook Salmon population from the East Fork Andreafsky River. The average ages of the total population, males only, and females only are shown separately. Age-1.1 fish were not available for the estimation of average age in brood year 1990, and their absence was ignored due to their rarity or absence in all other brood years (Table S.A.5).

Supplementary Figure S.A.3. Estimated productivity (recruits per spawner) by brood year from run reconstruction for the Kogrukluk River Chinook Salmon population. Brood year is defined as the year of the escapement that produced recruits. Spawners are estimated as the escapement above the monitoring weir in a single return year. Recruits are estimated as all returns (escapement plus harvest) originating from a single brood year. Replacement level is shown by the dashed line.

Supplementary Figure S.A.4. Estimated average (a) brood recruit age by brood year and (b) escapement age by return year for the Chinook Salmon population from the Kogrukluk River. The average ages of the total population, males only, and females only are shown separately. Age-1.1 fish were not available for the estimation of average age in brood year 1977, and their absence was ignored due to their rarity or absence in all other brood years (Table S.A.11).
